KEY_Lesson12_Pandas-Subsetting

July 10, 2019

1 Subsetting Pandas DataFrames

You now know how to read external datasets into pandas. Let's put those skills to use and read in the tips dataset again:

```
[]: # mount Google Drive
from google.colab import drive
drive.mount('/content/gdrive')
```

Drive already mounted at /content/gdrive; to attempt to forcibly remount, call drive.mount("/content/gdrive", force_remount=True).

Take a look again at the beginning of the tips DataFrame:

```
[]: # view the beginning of tips tips.head()
```

```
[]:
      total_bill
                  tip
                          sex smoker
                                    day
                                            time size
          16.99
                 1.01 Female
                                 No
                                     Sun
                                          Dinner
   1
          10.34 1.66
                         Male
                                 No Sun
                                          Dinner
   2
          21.01 3.50
                         Male
                                 No Sun Dinner
                                                     3
   3
                                                     2
          23.68 3.31
                        Male
                                 No Sun Dinner
          24.59
                3.61 Female
                                 No
                                     Sun
                                          Dinner
```

What if we decided we didn't want to keep all of the data recorded in this dataset? To do that, we need to learn how to subset DataFrames. Subsetting means taking a dataset and pulling out a small portion of it that we're interested in.

First, we'll look at a single column (you can use head to keep the printed result short):

```
[]: tips['day'].head(10)
```

- []: 0 Sun
 - 1 Sun
 - 2 Sun
 - 3 Sun

```
4 Sun
5 Sun
6 Sun
7 Sun
8 Sun
9 Sun
Name: day, dtype: object
```

We use the square brackets [] after the name of the DataFrame to tell pandas that we want to look at one of the columns. We put the name of the column in quotes to tell pandas exactly which column we want to look at. Try subsetting the total_bill column:

```
[]: # subset the total_bill column
   tips['total_bill'].head(10)
[]: 0
         16.99
   1
         10.34
   2
         21.01
   3
         23.68
   4
         24.59
   5
         25.29
   6
          8.77
   7
         26.88
   8
         15.04
   9
         14.78
   Name: total_bill, dtype: float64
```

pandas simply showed us the result of subsetting the column, but it didn't save the result anywhere. Try saving the total_bill column to a new variable, bills:

```
[]: # save the total_bill column to a variable bills = tips['total_bill']
```

We can also pull out multiple columns at a time to create a new DataFrame. If we were only interested in the total_bill and tip, we can subset them like this:

```
[]: tips[['total_bill', 'tip']].head(10)
      total_bill
tip
   0
           16.99
                  1.01
   1
           10.34
                  1.66
   2
           21.01
                  3.50
   3
           23.68 3.31
   4
           24.59
                  3.61
   5
           25.29 4.71
            8.77
   6
                  2.00
   7
           26.88 3.12
   8
           15.04
                  1.96
           14.78 3.23
```

Does that look familiar? Instead of putting a single string between the square brackets, we put a whole list of strings – you can tell it's a list by the second set of square brackets. Now you try: subset the columns total_bill, tip, and time and save the result to a variable called

tips_subset:

```
[]: # subset three columns and save to a new variable
tips_subset = tips[['total_bill', 'tip', 'time']]

# take a look at the beginning of the new DataFrame
tips_subset.head()
```

```
[]:
       total_bill
                     tip
                             time
                    1.01
            16.99
                           Dinner
   1
            10.34
                    1.66
                           Dinner
   2
            21.01
                    3.50
                           Dinner
   3
            23.68
                    3.31
                           Dinner
   4
            24.59
                    3.61
                           Dinner
```

Now we've learned how to subset columns. How do we subset rows? We use a method of DataFrame called iloc. When you see iloc, think "index location" – because we want to get the location where the row is a certain index. Let's try it:

```
[]: tips.loc[1]
[]: total bill 10.34
```

```
[]: total_bill 10.34
tip 1.66
sex Male
smoker No
day Sun
time Dinner
size 3
Name: 1, dtype: object
```

That showed us the row with an index of 1. Similarly to subsetting columns, we can also subset multiple rows:

```
[]: tips.iloc[[0,1,2]]
```

```
[]:
       total_bill
                                                     time
                      tip
                               sex smoker
                                             day
                                                            size
                     1.01
                                                                2
    0
             16.99
                           Female
                                             Sun
                                        No
                                                   Dinner
    1
             10.34
                     1.66
                                                               3
                              Male
                                        No
                                             Sun
                                                   Dinner
    2
                     3.50
                                                               3
             21.01
                              Male
                                        No
                                             Sun
                                                  Dinner
```

That gave us a smaller DataFrame where the rows have an index of 0, 1, or 2. We can do the same thing with slicing syntax:

```
[]: tips.iloc[0:3]
```

```
[]:
       total_bill
                      tip
                                             day
                                                    time
                                                           size
                               sex smoker
             16.99
                                                               2
    0
                     1.01
                           Female
                                             Sun
                                                  Dinner
                                        No
    1
             10.34
                     1.66
                              Male
                                        No
                                             Sun
                                                  Dinner
                                                               3
    2
            21.01
                    3.50
                                                               3
                              Male
                                        No
                                            Sun
                                                  Dinner
```

Notice that this does the same thing as calling head with a value of 3:

```
[]: tips.head(3)
```

```
[]:
       total bill
                                                           size
                      tip
                               sex smoker
                                            day
                                                    time
    0
             16.99
                    1.01
                           Female
                                            Sun
                                                  Dinner
                                                              2
                                        No
             10.34
                    1.66
                                                               3
    1
                             Male
                                            Sun
                                                  Dinner
                                        No
    2
            21.01
                    3.50
                                            Sun
                                                              3
                             Male
                                        No
                                                  Dinner
```

105

15.36

1.64

Male

What if we want to grab some rows in the middle of the DataFrame? Try subsetting rows 100 through 105:

```
[]: # subset rows 100 through 105
   tips.iloc[100:106]
[]:
         total_bill
                                             day
                       tip
                                sex smoker
                                                     time
                                                            size
   100
                                                               2
               11.35
                      2.50
                             Female
                                        Yes
                                             Fri
                                                   Dinner
   101
                                                               2
               15.38
                      3.00
                             Female
                                        Yes
                                             Fri
                                                   Dinner
   102
               44.30
                      2.50
                                                               3
                             Female
                                        Yes
                                             Sat
                                                   Dinner
   103
               22.42
                      3.48
                             Female
                                        Yes
                                             Sat
                                                   Dinner
                                                               2
   104
               20.92 4.08
                             Female
                                                   Dinner
                                                               2
                                         No
                                             Sat
```

We can even subset rows and columns in the same line of code. What do you think the following cell will do?

Sat

Yes

Dinner

2

```
[]: tips.loc[5:10][['total_bill', 'day', 'time']]
[]:

                    Sun
                          Dinner
   10
             10.27
                          Dinner
                    Sun
```

Sometimes we don't know exactly which row(s) we want to subset ahead of time. What if we want to subset rows that have a certain value in the time column? We don't want to scroll through hundreds of rows to find them. The good news is: we don't have to! Let's use the method called query. Inside the parentheses of query we'll enclose a statement in quotes with the name of the column and an expression.

```
[]: tips.query('time == "Lunch"')
```

[]:		total_bill	tip	sex	smoker	day	time	size
	77	27.20	4.00	Male	No	Thur	Lunch	4
	78	22.76	3.00	Male	No	Thur	Lunch	2

                                    Yes
```

[68 rows x 7 columns]

The above cell showed us all the rows where time is equal to "Lunch". We had to enclose "Lunch" in quotes above because it's not the name of a column, but a value within the time column.

Now you try: subset the rows where the waitress is female and save it to a variable, female:

```
[]: # subset rows with a female waitress and save it to a variable
female = tips.query('sex == "Female"')

# take a look at the beginning
female.head()
```

```

                                                 Dinner
                                                              3
```

Now lets do the same for males. Subset the male waiter data and save it to a variable, male:

```
[]: # subset the male waiters and save it
male = tips.query('sex == "Male"')

# look at the beginning
male.head()
```

```
[]:
       total_bill
                      tip
                            sex smoker
                                          day
                                                  time
                                                        size
             10.34
                    1.66
                                                            3
   1
                           Male
                                     No
                                          Sun
                                               Dinner
   2
            21.01
                                                            3
                    3.50
                           Male
                                     No
                                          Sun
                                               Dinner
   3
            23.68
                    3.31
                                                            2
                           Male
                                     No
                                          Sun
                                               Dinner
   5
            25.29
                    4.71
                           Male
                                     No
                                          Sun
                                               Dinner
                                                            4
              8.77
                    2.00
                           Male
                                          Sun
                                               Dinner
                                                            2
                                     No
```

How would you determine the number of male waiters in this DataFrame? Think back to the

last lesson when we used the len function.

```
[]: # number of males
len(male)
```

[]: 157

How about the number of female waitreses?

```
[]: # number of females len(female)
```

[]: 87

We can use query on multiple columns at a time. Let's find out how many tables were served by a female waitress on a Sunday.

```
tips.query('sex == "Female" and day == "Sun"')
         total_bill
                                                            size
[]:
                       tip
                                sex smoker
                                              day
                                                     time
   0
               16.99
                                                               2
                      1.01

```

We used the ampersand symbol (&) or the keyword and to chain together two statements inside the query function. Both statements have to be true for a row to be included.

Besides checking whether values are equal using ==, we can also use greater than, less than, greater than or equal, etc. Try subsetting the rows where the bill is greater than \$15 and the tip is less than \$2:

```
[]: # subset by bill and tip
    tips.query('total_bill > 15 & tip < 2')
[]:
         total_bill
                                                             size
                       tip
                                sex smoker
                                               day
                                                       time
                      1.01
                                                                2
               16.99

```

Instead of the ampersand (&) we can use the pipe (|) or the keyword or to represent a query where *one* of the two conditions must be fulfilled. Try subsetting where the bill is greater than \$15 or the tip is greater than \$5:

```
[]: # subset by bill or tip
tips.query('total_bill > 15 | tip > 5')
```

[165 rows x 7 columns]

Congrats on making it to the end of this lesson – we learned a lot!

- How to use square brackets to subset columns.
- How to use iloc to subset rows.
- How to use iloc and square brackets at the same time.
- How to use query to find rows where the column has a certain value.

 $[\]$:
